Abstract

These European Society for Clinical Microbiology and Infectious Diseases and European Confederation of Medical Mycology Joint Clinical Guidelines focus on the diagnosis and management of mucormycosis. Only a few of the numerous recommendations can be summarized here. To diagnose mucormycosis, direct microscopy preferably using optical brighteners, histopathology and culture are strongly recommended. Pathogen identification to species level by molecular methods and susceptibility testing are strongly recommended to establish epidemiological knowledge. The recommendation for guiding treatment based on MICs is supported only marginally. Imaging is strongly recommended to establish epidemiological knowledge. The recommendation for guiding treatment based on MICs is supported only marginally. Imaging is strongly recommended to determine the extent of disease. To differentiate mucormycosis from aspergillosis in haematological malignancy and stem cell transplantation recipients, identification of the reverse halo sign on computed tomography is advised with moderate strength. For adults and children we strongly recommend surgical debridement in addition to immediate first-line antifungal treatment with liposomal or lipid-complex amphotericin B with a minimum dose of 5 mg/kg/day. Amphotericin B deoxycholate is better avoided because of severe adverse effects. For salvage treatment we strongly recommend posaconazole 4 × 200 mg/day. Reversal of predisposing conditions is strongly recommended, i.e. using granulocyte colony-stimulating factor in haematological patients with ongoing neutropenia, controlling hyperglycaemia and ketoacidosis in diabetic patients, and limiting glucocorticosteroids to the minimum dose required. We recommend against using deferasirox in haematological patients outside clinical trials, and marginally support a recommendation for deferasirox in diabetic patients. Hyperbaric oxygen is supported with marginal strength only. Finally, we strongly recommend continuing treatment until complete response demonstrated on imaging and permanent reversal of predisposing factors.

Introduction

Mucormycosis is a very aggressive invasive fungal disease [1,2]. It is a fungal emergency that affects a variety of patient groups [3]. The disease, previously termed zygomycosis [4], is caused by mucoralean fungi, which have collectively also been called Mucormycetes [5,6]. However, we prefer to use the name of the order, i.e. Mucorales.

The genera causing the majority of mucormycoses are Rhizopus, Mucor, Lichtheimia (previously classified as Absidia), Cunninghamella, Rhizomucor, Apophysomyces and Saksenaea [7]. Granulocytopenia, immunosuppression, diabetes and penetrating trauma are the most prevalent predisposing diseases associated with mucormycosis [7]. Cavitary pulmonary disease due to Rhizopus hamathallicus has been described as a distinct pattern in diabetic patients in India [8]. Besides patients with these typical risk factors, mucormycosis has been reported in otherwise healthy individuals in India and China, e.g. in the forms of renal mucormycosis and chronic (sub-)cutaneous infections due to Mucor irregularis (Rhizomucor variabilis) [8–16]. Recently, the different clinical manifestations have been reviewed [17].

Arnold Paltauf reported the first histologically proven case of Mucosis mucarina at the University of Graz, Austria in 1885 [18]. Though the disease has been known for a long time, the epidemiology is not well defined. In a study from France mucormycosis had increasingly been diagnosed over the past years, culminating in a general population incidence of 1.2 per million/year [19]. Two further studies from Spain and California report incidences between 0.4 and 1.7 cases per million population/year [20,21]. In patients with haematological malignancy mucormycosis was less common than invasive aspergillosis, but mucormycosis independently predicted death in these patients [22,23]. Lymphocytopenia has recently been identified as independently predicting death in this setting [24]. Mortality rates in patients with mucormycosis remain high and in recent reports they ranged from 24% to 49% [7,19,25,26].

Guidance for diagnosis and treatment of mucormycosis is needed, because in rare diseases it is difficult to execute comparative clinical trials and to accumulate substantial personal experience. This is particularly true for a disease that is likely to be underdiagnosed and in which individual prognosis is driven by early treatment [2,27]. This guidance document will provide help to improve management of invasive mucormycosis.

Methods

An expert group (OAC, SAA, AC, ED, AHG, KL, FL, LP, GP and AS) was set up by the European Society of Clinical Microbiology and Infectious Diseases (ESCMID) Fungal Infection Study Group (EFISG) and the European Confederation of Medical Mycology (ECMM) and searched the literature using the search string ‘mucormycosis’ OR zygomycosis NOT entomophthoramyces* NOT phycomycosis*”. Documents and views were shared by email, teleconferences and face-to-face meetings during April 2012 to April 2013. Once a structured first consensus was reached the preliminary recommendations were presented to the whole group, i.e. the other authors, discussed, developed further and finalized as a group consensus. The methods to evaluate the quality of evidence and to reach group consensus recommendations are described in the context of the ESCMID clinical guidelines on Candida infection [28]. For the present guideline we applied the same system to diagnostic procedures. The definition of the strength of recommendation is given in Table 1. The quality of the published evidence is defined in Table 2(a). To increase transparency regarding the evaluation of available evidence we added an index (Table 2b) to the level II recommendations, where appropriate. Of note, the evaluation of the strength of recommendation and of the quality of evidence was performed in two separate evaluations, so allowing for a recommendation strongly supporting a procedure even if there is a lower level of evidence. If ESCMID EFISG and ECMM marginally support a recommen-
Recommendations on diagnostics in mucormycosis

**Conventional microbiological methods.** Direct microscopy of clinical specimens, preferably using optical brighteners, allows a rapid presumptive diagnosis of mucormycosis. Blankophor and Calcofluor bind to chitin and cellulose and fluoresce in ultraviolet light [29]. Hyphae of Mucorales have a variable width (6–25 μm), are non-septate or pauci-septate and have an irregular, ribbon-like appearance. The angle of branching is variable and includes wide-angle (90°) bifurcations. Culture of specimens is considered an essential investigation. Although the sensitivity of culture is not optimal, it allows identification and susceptibility testing of the isolate in case of growth. Histopathological examination of tissue specimens may allow differentiation between hyphae of Aspergillus or morphologically related fungi, and hyphae of Mucorales, which is important for treatment decisions. Mucormycosis is characterized by prominent infarcts, angioinvasion and perineural invasion.

**Evidence—**The value of fluorescent whiteners for computed tomography (CT) -guided percutaneous lung biopsy specimens was assessed in 61 patients with CT findings highly suggestive of an invasive fungal infection [30]. Calcofluor white staining revealed fungal elements in 49 specimens (80%) and allowed the differentiation between septate (n = 36) and non-septate (n = 13) hyphae. The DNA of mucoralean fungi was detected by PCR in all samples with non-septate hyphae. Calcofluor white analysis was considered false negative in 5% of specimens [30]. In a patient with acute myelogenous leukaemia and periodontal mucormycosis, intraoperative calcofluor white fluorescence microscopy was used for a prompt diagnosis and to guide the extent of surgical debridement. Maxillary biopsies with intraoperative calcofluor white analysis were used to rule out persistent oral mucormycosis in this case [31].

Mucorales grow well on both non-selective and fungus-selective media and the growth tends to be rapid, i.e. covers the entire plate in a few days. The recovery of Mucorales from tissues may be problematic and negative cultures seem to be correlated with aggressive processing of the specimens before plating. Grinding of specimens should therefore be avoided [32]. The specimen is preferably incubated at 37°C [33–35].

Histopathological review of tissue samples from 20 patients with rhinocerebral disease (n = 11), pulmonary disease (n = 6), or a fungus ball (n = 3) revealed that the inflammatory responses were predominantly neutrophilic (50%), pyogranulomatous (25%) or absent (20%). Invasive disease was characterized by prominent infarcts (94%), angioinvasion (100%) and prominent perineural invasion (90%) in biopsies that contained nerve structures for evaluation. The presence of septa in the hyphae was rare and hyphal branching angles varied from 45 to 90° [36]. Pulmonary mucormycosis in cancer patients (n = 20, 19 patients with haematological malignancy) is characterized by angioinvasion (100%), haemorrhagic infarction (90%), coagulative necrosis (85%) and intra-alveolar haemorrhage (85%). Neutropenic patients had more extensive angioinvasion compared with non-neutropenic patients [37]. In recent registries of mucormycosis, histopathology led to the diagnosis in 63% [26] and 66% [7] of cases. The diagnosis of 75 cases from an Indian tertiary-care hospital was based on histopathology [38].

In a separate report three cases of mucormycosis were diagnosed by immunohistochemistry using monoclonal antibodies against somatic antigens of *Rhizopus oryzae*; two of three had been misclassified as aspergillosis based on histopathology alone [39].

**Recommendations—**Direct microscopy of clinical specimens preferably using optical brighteners and culture is strongly recommended for the diagnosis of mucormycosis. Histopathology may allow differentiation of mucormycosis from aspergillosis—and other hyalohyphomycoses and phaeohyphomycoses—and is strongly recommended. Notably, scrapings do not reliably prove tissue invasion. Any microscopic examination should evaluate morphology, width, branching angle and septation. Direct microscopy is not useful for species identification, and immunohistochemistry is only marginally supported for the diagnosis of mucormycosis due to the lack of commercially available monoclonal antibodies and clinical validation. For further recommendations refer to Table 3.

**Detection of antigen and Mucorales-specific T cells.** There are no standardized assays available for the detection of Mucorales-specific antigens. The healthcare provider should have a high level of suspicion that the patient has mucormycosis rather than aspergillosis in patients with CT lesions that are highly suggestive for invasive fungal disease, specifically if *Aspergillus galactomannan* test results on serum and broncho-alveolar lavage are negative [40]. Of note, 1,3-β-D-glucan is a common component of the cell wall of a wide variety of fungi but not of the Mucorales.

**Evidence—**At two centres with a high autopsy rate, mucormycosis diagnosis was missed using a diagnostic strategy with regular galactomannan testing of serum samples [41,42]. In a study of breakthrough invasive mould infections in patients...
treated with caspofungin, two cases of mucormycoses occurred among eight patients in whom galactomannan tests remained negative [43].

In vitro analysis of culture supernatants of different species causing mucormycosis \((n = 8, \text{four different species})\) revealed a low antigen reaction compared with other mould isolates, presumably because of their low cell wall 1,3-\(b\)-D-glucan concentrations [44]. Three patients with mucormycosis had negative 1,3-\(b\)-D-glucan results in a multicentre evaluation of the performance of the 1,3-\(b\)-D-glucan test for the diagnosis of invasive fungal infections [45].

Mucorales-specific T cells were detected by an enzyme-linked immunospot (ELISPOT) assay in three haematological patients developing invasive mucormycosis at diagnosis and throughout the entire course of the invasive disease but not for long after resolution of the infection. None of the 25 control patients without mucormycosis had Mucorales-specific T cells [46].

Recommendations—The use of galactomannan detection is moderately supported for the diagnosis of invasive mucormycosis. In patients with a possible invasive fungal infection, negative galactomannan test results in serum and BAL increase the likelihood of invasive mucormycosis. 1,3-\(\beta\)-D-Glucan testing is not recommended for the diagnosis of invasive mucormycosis. For further recommendations refer to Table 3.

Molecular-based methods for direct detection. Evidence—An in-house semi-nested PCR that targets the 18S ribosomal DNA of Mucorales was evaluated on fresh tissue specimens in two prospective studies [30,47]. In the first study, PCR was performed on 56 respiratory biopsy specimens obtained by different procedures from immunocompromised patients suspected of having a mould infection. The PCR was positive in six samples with histopathological detection of Mucorales hyphae but culture was positive in only two of these samples. One false-positive result was obtained (2% of samples tested) [47]. The second study was conducted on CT-guided percutaneous lung biopsy specimens obtained from 46 patients with a haematological malignancy and 15 patients with solid-organ transplantation. PCR detected mucoralean fungi in all specimens with non-septate hyphae \((n = 13, \text{sensitivity } 100\%)\) whereas culture remained negative in five cases [30].

The performance of the same semi-nested PCR as described above was also evaluated on formalin-fixed paraffin-embedded tissue specimens in two different studies [48,49]. Mucorales PCR was positive in 22 of 27 tissue specimens from patients with a haematological malignancy or a haematopoietic stem cell transplant who were diagnosed with mucormycosis [48] and in 14 of 23 specimens from patients with the diagnosis of mucormycosis based on histopathology [49]. The failure to amplify specific DNA might result from fungal DNA concentrations below detection limits, a focal infection with varying amounts of fungal elements within the tissue or the destruction of DNA during formalin fixation. In four cases no human \(\beta\)-globin DNA could be detected by the control PCR [49]. A recent exercise evaluated a pan-fungal real-time PCR-based technique in formalin-fixed paraffin-embedded tissue specimens [50]. In a total of 89 biopsies from patients with invasive fungal diseases the average

sensitivity of the PCR assay was 89% and Mucorales were detected in 11% of biopsies, although the technique exhibited some limitations to detect *Rhizopus microsporus*, *Rhizopus oryzae* and *Saksenaea vasiformis* [50]. In an interlaboratory evaluation of the reproducibility of an internal transcribed spacer (ITS) PCR performed on formalin-fixed paraffin-embedded tissue specimens from experimentally infected mice, positive results were obtained in 93% of samples with 30 slide cuts of 10 μm. Sensitivity decreased to 27% when tissue quantity was reduced to one section. Interlaboratory reproducibility was excellent [50,51]. Mucorales DNA was detected in 40–60% of plasma samples with real-time PCR as early as one day post-inoculation in a rabbit model of experimental pulmonary mucormycosis [52].

**Recommendations**—Currently, in the absence of a standardized test, the use of molecular methods on both fresh clinical material and paraffin slides for the diagnosis of mucormycosis is moderately supported. Fresh material is preferred over paraffin-embedded tissue because formalin damages DNA. For further recommendations refer to Table 3.

**Genus and species identification.** There is no strong evidence that identification to the genus/species level may be important to guide treatment. Identification to the species level is of interest for a better epidemiological knowledge of mucormycosis and may be of value for outbreak investigation. Molecular techniques are more reliable than phenotypic identification of Mucorales in culture to the species level. Sequencing of ITS is currently the best molecular technique for species identification. Carbon assimilation profiles using the commercialized kits ID32C and API 50 CH (bioMérieux, Marcy l’Etoile, France) allowed precise and accurate identification of Mucorales to the species level [53]. Alternative techniques such as matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry are promising but not yet validated for all species.

**Evidence**—Although some genera, such as *Cunninghamamella*, may be associated with a higher mortality rate in patients [3,5] and have been shown to be more virulent in experimental models [54], there is currently sparse evidence that identification of the causative Mucorales to the genus and/or species level could guide the choice of the antifungal treatment [55,56].

In contrast, identification to the species level is of interest for better epidemiological knowledge of the disease. In particular, the clinical picture may be different depending on the species [3,5,57]. Moreover, species identification could be valuable for investigation of healthcare-associated mucormycosis and outbreaks [58].

Identification of Mucorales in culture by standard mycological methods such as morphology is notoriously difficult because the different species share similar morphological characteristics. This has been highlighted by recent molecular description of cryptic species that can hardly be distinguished morphologically [59–62]. Moreover, some species fail to sporulate in standard media, precluding a timely and easy morphological identification [63]. A comparison of morphological versus molecular identification of 19 isolates of Mucorales from patients with mucormycosis showed that identification by morphology was erroneous in >20% of the cases [64]. A high level of concordance (~90%) between morphology and molecular identification may be only seen in reference laboratories [65].

Several DNA targets have been evaluated for a reliable identification to the species level. The best informative target should have a large interspecific (between species) and a low intraspecific (within a given species) sequence variability. Moreover, a comprehensive and accurate database must be available. In a study of 54 isolates from 16 different species it has been shown that ITS sequencing was a reliable and accurate method for identification to the species level [66]. Similar results were obtained by other authors [67,68]. Based on published results and expert opinions, the CLSI has proposed ITS sequencing as a valuable method for identification of genus and also of species [69]. More recently, the International Society for Human and Animal Mycology (ISHAM) working group on fungal molecular identification has recommended using ITS sequencing as a first-line method for species identification of Mucorales [70]. Other DNA targets have also been evaluated including 18S, 28S, cytochrome b or FTR1 [71–75] and could be used as alternatives but for some of these targets there is less evidence of their usefulness.

Alternative methods for rapid identification of filamentous fungi in clinical microbiology laboratories have been recently evaluated. In particular, using ID32C strips or API 50 CH carbon assimilation strips and 57 Mucorales strains, intraspecies variation was found to be low, whereas large differences were found between genera and species, allowing identification to the species level for all included strains except for *Rhizopus oryzae*. The clustering of isolates based on their carbon assimilation profiles was in accordance with DNA-based phylogeny of Mucorales [53]. MALDI-TOF mass spectrometry may be of interest although limited data are currently available for Mucorales [76–78]. In an analysis of 103 filamentous fungi by MALDI-TOF, the eight tested Mucorales were correctly identified to species level [77]. In a more recent study it was shown that 34 strains of *Lichtheimia* spp. could be reliably identified by comparison to an in-house database constructed
with 19 strains belonging to eight species [78]. Although MALDI-TOF identification of Mucorales seems promising, more data are needed to validate this technique and commercially available databases should be validated.

**Recommendations**—Identification to the genus and species level is strongly supported for a better epidemiological knowledge of the disease. Guiding treatment by identifying to the genus level is marginally supported. Carbon assimilation is moderately supported and molecular identification is strongly supported in comparison to morphology. The best technique for molecular identification is ITS sequencing. There are currently limited data for MALDI-TOF as an identification method. For further recommendations refer to Table 4.

**Susceptibility testing. Evidence**—European Committee on Antimicrobial Susceptibility Testing (EUCAST) and CLSI (CLSI M38-A2) [79,80] reference microdilution methods are used as standard assays for antifungal susceptibility testing of Mucorales. Using methods other than the reference assays such as Etest® [21,55] or XTT assay [81,82] remains investigational. Except for posaconazole, moderate (<80%) correlation of Etest® and Sensititre YeastOne® with the CLSI M38-A2 method was noted in antifungal susceptibility testing of Mucorales [21,79]. Rapid (within 6–8 h) susceptibility testing can be achieved with the XTT assay [81]. Currently, there are no validated MIC breakpoints for any of the drugs against Mucorales [83,84]. Rapid (<6 h) susceptibility testing is strongly supported in comparison to morphology. The best technique for molecular identification is ITS sequencing. There are currently limited data for MALDI-TOF as an identification method. For further recommendations refer to Table 4.

**NTS**, internal transcribed spacer; MALDI-TOF, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry; QoE, quality of evidence; RFLP, restriction fragment length polymorphism; SoR, strength of recommendation.

Of those infected with strains with an amphotericin B MIC of ≥1 μg/mL, 43% failed to respond [83]. Animal studies for determination of in vitro–in vivo correlation are also limited. In murine models of infections due to *Rhizopus microsporus* [84] and *Rhizopus oryzae* [85] posaconazole was shown to be more effective in infections due to strains with an MIC of 0.25 μg/mL compared with those with an MIC of 2 μg/mL. On the other hand, a low minimum fungicidal concentration, i.e. 0.5 μg/mL of posaconazole was associated with response in mice infected with *Rhizopus oryzae*. High posaconazole minimum fungicidal concentration values, i.e. >16 μg/mL, correlated with clinical failure in a similar murine model [82].

Antifungal susceptibility testing of the strains in the order Mucorales has been performed mostly for epidemiological purposes. The data presented in these studies provide significant clues for the expected susceptibility profiles and are useful to evaluate genus-, species- and strain-based variations in susceptibility. Fluconazole [84,86,87], voriconazole [84,86–91], echinocandins [84,87,90,91] and flucytosine [84,87,88,90,91] lack meaningful in vitro activity against Mucorales. In general, amphotericin B and posaconazole are the most active drugs in vitro [84,86–92]. The comparative activities of amphotericin B and posaconazole may vary depending on the genus and species of the infecting strain. Although amphotericin B yields lower MICs against *Mucor circinelloides* compared with posaconazole [55,92], posaconazole MICs are lower than those of amphotericin B against *Cunninghamella bertholletiae* [92,93]. On the other hand, high MICs of both amphotericin B and posaconazole have been reported for strains of *Cunninghamella echinulata* [93]. Species-specific differences in azole and terbinfine susceptibilities are noted particularly for *Rhizopus* and *Mucor* [84,85,88,90]. Finally, strain-based variations have also been described, as for
posaconazole susceptibility of *Rhizopus oryzae* strains [85,91]. Despite the lack of preference for its use in treatment of mucormycosis, itraconazole MICs are relatively low for a number of strains, including those of *Rhizomucor* [90,92] and *Licthheimia* [86,88,90,92].

Efficacy of combination therapy was addressed in murine models of mucormycosis. Improved survival was observed with the combination of amphotericin B lipid complex and caspofungin compared with monotherapy and untreated controls in diabetic ketoacidotic mice infected with a more virulent brain isolate of *Rhizopus oryzae*. However, improved organ clearance was not achieved with combination therapy [94]. In a murine model of disseminated mucormycosis caused by *Rhizopus oryzae*, posaconazole combined with amphotericin B at low dose (0.3 mg/kg/day) prolonged survival, and reduced tissue burden was observed compared with monotherapy and controls. However, it was not superior to amphotericin B (0.8 mg/kg/day) alone [95].

*In vitro* combination studies have also been performed to explore the interaction of antifungal agents against members of the order Mucorales. The previously published reports include data for combinations of amphotericin B and rifampin (69% synergy, 31% indifference), amphotericin B and fluconazole (100% indifference), amphotericin B and terbinafine (80% indifference, 20% synergy), and terbinafine and voriconazole (56% indifference, 44% synergy) for miscellaneous genera of Mucorales (n = 35) [96]. Data are also available for combinations of amphotericin B and posaconazole: miscellaneous genera (n = 21) with indifference in all strains [91]; *Rhizopus oryzae* (n = 11), indifference in all strains [89]. The above combination was more synergistic against hyphae than conidia of miscellaneous genera (n = 30) [97]. Further data are available for amphotericin B and anidulafungin (miscellaneous genera, n = 21, indifference in 20 and synergy in one strain) [91], for posaconazole and caspofungin (miscellaneous genera, n = 12; synergy in all strains) [98], for posaconazole and anidulafungin (miscellaneous genera, n = 21, indifference in all strains) [91], and for itraconazole and terbinafine (miscellaneous genera, n = 17; synergy in 14 strains) [99].

Overall, and of major importance, the clinical significance of these and other *in vitro* and *in vivo* combination data remains uncertain [100].

**Recommendations**—Given the relative lack of clinical breakpoints and still limited sufficient data to indicate a clear reading correlation between MIC or minimum fungidal concentration values and clinical outcome, use of antifungal susceptibility testing for guiding treatment in mucormycosis is recommended only with marginal strength. Susceptibility testing for attaining epidemiological data is strongly recommended. For further recommendations refer to Table 5.

**Imaging.** There are obvious limitations for the differential diagnosis between filamentous fungal infections if no histological or cultural evidence is available. Some imaging characteristics have been evaluated regarding their potential to differentiate between fungal genera.

*Evidence*—The halo sign, i.e. a ring of ground glass opacity surrounding a nodular infiltrate, and the air crescent sign, are clinical criteria indicating lower respiratory tract fungal disease [101], but they were not predictive of the genus of an invasive fungal pathogen in a historical control study [102]. The reversed halo sign (also known as inverted halo sign or atoll sign) is an area of ground glass opacity surrounded by a ring of consolidation (Fig. 1). In an uncontrolled study on 189 patients treated for proven or probable invasive fungal pneumonia the reversed halo was present in 19% of patients

with mucormycosis, in <1% of patients with invasive aspergillosis, and in no patient with fusariosis. The majority of patients with a reversed halo sign had undergone haematopoietic stem cell transplantation for acute myelogenous or chronic lymphatic leukaemia [103]. As a wide range of infectious and non-infectious diseases may present with a reversed halo sign on CT, the diagnostic value of this finding depends on the pre-test probability [104].

Patients with more than ten nodular infiltrates were more likely to have mucormycosis than aspergillosis in one historical control study [102], whereas in a separate patient series this was not the case [104].

If mucormycosis is the suspected diagnosis, histological proof is urgently needed. Computed tomography-guided needle biopsy was successfully applied in 61 patients with possible invasive fungal diseases. Mucormycosis was diagnosed in 13 (21%) [30]. In a separate series of 56 patients with pulmonary nodular infiltrates on CT, biopsy identified proven mucormycosis in six (11%) [47]. In both series a prerequisite was a minimum platelet count of 50 000/µL, which can be achieved by platelet transfusion [30].

Pleural effusion independently predicted mucormycosis in a historical control study (n = 16) [102], and was found in all patients of a second, independent series (n = 18) [104].

In a population of patients with haematological malignancies (n = 59) about 20% of patients had disseminated disease, so that cranial, thoracic and abdominal imaging studies appear warranted [105]. In a historical control study, 31% of mucormycosis patients had sinus involvement [102].

In the 1980s, in two series (n = 10, each) of patients with poorly controlled diabetes and mucormycosis cranial CT revealed typical signs of sinusitis and orbital involvement [106,107].

Sinusitis was more commonly associated with mucormycosis than with invasive aspergillosis in patients with haematological disease [102]. Mucosal thickening without air/fluid levels was the usual finding in two series comprising ten patients each [106,107].

In case of bone destruction diagnosed on CT, magnetic resonance imaging should be used to reveal the full extent of disease [108,109]. In an institutional series of patients with mucormycosis (n = 27) approximately half of the patients with sinus involvement showed intracranial spread of disease [110].

Recommendations—In patients with haematological malignancy it is recommended that the possibility of mucormycosis be considered, particularly in the case of a lung infiltrate with a reversed halo sign on CT. If mucormycosis is a potential differential diagnosis, biopsy should be pursued. Once mucormycosis has been proven in a patient with underlying

malignancy, cranial, thoracic and abdominal imaging studies are recommended to determine the extent of disease. For further recommendations refer to Table 6.

**Recommendations on treatment of mucormycosis**

**Prophylaxis. Evidence—** In two well-designed clinical trials evaluating primary antifungal prophylaxis during high-risk periods of immunosuppressed patients, i.e. during long-lasting neutropenia in acute myelogenous leukaemia and during graft-versus-host disease with augmented immunosuppression, the incidence rates of invasive fungal diseases were successfully reduced by posaconazole 200 mg three times daily. Mucormycosis only occurred in the comparator treatment arms of the trials, i.e. fluconazole or itraconazole, but the overall rate was very low [111,112]. The prospective SEIFEM-B 2010 registry on newly diagnosed acute myelogenous leukaemia (n = 515) compared posaconazole with itraconazole prophylaxis and no mucormycosis cases were diagnosed in either group [113]. While fluconazole [114] and voriconazole [115] are not active against mucormycosis, itraconazole may yield some activity, but may be inferior to posaconazole [116].

In immunosuppressed patients with a previous diagnosis of mucormycosis (n = 3) surgery in combination with secondary antifungal prophylaxis successfully prevented recurrence [117]. Another study reported a single case in support of this approach [118].

**Recommendations—** During periods of graft-versus-host disease with augmented immunosuppression and during outbreak situations posaconazole primary prophylaxis is recommended with marginal support for the specific prevention of mucormycosis. We acknowledge that this is a rather artificial scenario, since prophylaxis of invasive aspergillosis will be given already. In patients with previous mucormycosis, surgical resection and individualized secondary antifungal prophylaxis are strongly supported. The last effective antifungal in the respective individual should be preferred. For further recommendations refer to Table 7.

**Fever-driven treatment. Evidence—** No clinical trial has been conducted evaluating the timing of fever-driven treatment directed against mucormycosis. In general, a diagnosis-driven antifungal treatment is preferable [119].

**Recommendations—** If institutional epidemiology advocates mucormycosis to be part of the antifungal spectrum, refer to drugs and doses used for targeted treatment.

**Targeted first-line treatment. Evidence—** In the field of mucormycosis no well-designed randomized clinical efficacy trial has been published. In a retrospective study on 30 patients combined with a literature analysis of 225 patients with mucormycosis, surgical debridement of lung involvement was associated with a decrease of mortality from 62% to 11%. Procedures were lobectomy, pneumonectomy or wedge resection and patients with non-disseminated disease were more likely to be treated surgically [120]. Two recent literature reviews documented higher survival rates with a combined modality approach of surgical and medical treatment [3,121]. A large institutional series reinforced the need for a combined therapeutic approach [38] and in posaconazole salvage treatment of mucormycosis the highest cure rates were achieved when surgery was part of the strategy [122]. A multivariate analysis from an ECMM case registry [7] and a retrospective analysis of a national case series also found surgery associated with survival [25]. Surgery is of major importance in rhino-orbito-cerebral locations, as evidenced in a retrospective study, where the impact of local control on survival was striking [123].

In an uncontrolled study in patients with haematological malignancy the 12-week mortality rate increased two-fold with medical treatment deferred for 6 or more days from onset of symptoms [27].

Murine models suggest that liposomal amphotericin B is more effective than the deoxycholate formulation against mucormycosis [124], and that for liposomal amphotericin B and amphotericin B lipid complex efficacy was dose-dependent [125]. Actually the lipid complex formulation reached higher lung concentrations and better fungal tissue clearance than liposomal amphotericin B [125]. Whereas both formulations had similar efficacy in neutropenic and diabetic ketoacidotic mice, liposomal amphotericin B was more effective in reducing

brain fungal burden [126]. In central nervous system disease amphotericin deoxycholate and liposomal amphotericin achieved the highest efficacy in a rabbit model; however, this model evaluated candidiasis [127].

In an uncontrolled retrospective study on patients with haematological malignancy multivariate analysis revealed treatment with liposomal amphotericin B 3 mg/kg/day to be independently associated with cure [105]. An analysis from the ECMM FungiScope™ registry (www.fungiscope.net) demonstrated that liposomal amphotericin B at an average dose of 5 mg/kg/day was associated with increased response and survival rates [26]. The ECMM mucormycosis registry (www.zygomyco.net) reported that a liposomal amphotericin B median dose of 5 mg/kg/day (range 3–10 mg/kg/day) leads to favourable response rates [7]. In invasive aspergillosis high-dose liposomal amphotericin B (10 mg/kg/day) caused significantly more renal toxicity than the standard dose of 3 mg/kg/day, but proved the general feasibility of high-dose regimens [128]. A subsequent non-comparative clinical trial evaluated the feasibility and efficacy of liposomal amphotericin B 10 mg/kg/day for the initial treatment of mucormycosis [129]. Renal toxicity was frequent (40%), but treatment was feasible in more than half of the patients; at week 12 the response rate was 45% [57].

First-line treatment with amphotericin B lipid complex 5 mg/kg/day has been reported in a very limited number of patients only [7,130]. In conjunction with the evidence from animal models, central nervous system involvement should be excluded if this formulation is to be used [126,127].

In immunocompetent mice amphotericin B prolonged survival, whereas for itraconazole and posaconazole there are heterogeneous effects depending on the fungal species used for infection [131–133]. The ECMM clinical registries reported successful first-line treatment with posaconazole in about 50–60% of patients [7,26]. Split doses of posaconazole yield higher exposure, so that posaconazole 200 mg four times daily is the preferred dosing regimen in mucormycosis treatment [134].

Concomitant treatment with an amphotericin B formulation and caspofungin has been described as successful in a limited number of predominantly diabetic patients with rhinocerebral mucormycosis [135].

Amphotericin B deoxycholate has been used as standard treatment when no alternative was available [3]. When the comparison to liposomal amphotericin B in fever-driven treatment provided objective proof of its substantial toxicity, the deoxycholate formulation was no longer appropriate, although it is still used where resources are a constraint [136,137]. Amphotericin B deoxycholate did not correlate with superior recovery in a multivariate analysis in a haematological malignancy population [105], in a large institutional series with a variety of underlying diseases [38], and most recently in an ECMM registry [7].

Recommendations—In patients with mucormycosis, surgery whenever possible is strongly recommended to be combined with medical treatment. Immediate treatment initiation is strongly supported to increase survival rates. Liposomal amphotericin B is the drug of choice and the dose should be at least 5 mg/kg/day. The use of amphotericin B deoxycholate is discouraged. For further recommendations refer to Table 8.

Salvage treatment. Evidence—Salvage treatment may be necessary because of refractoriness of disease, or because of intolerance towards previous antifungal therapy, or because of a combination of both.

In the posaconazole compassionate use programme, investigators were allowed to switch between two oral suspension dosing regimens, i.e. 200 mg four times daily and 400 mg twice daily. Rates of complete and partial response [138] as well as survival approached 80% in patients with refractory disease and in patients intolerant to previous therapy [122]. A second analysis of a larger population from the same programme described a treatment response rate of 60% (overlap between both articles was 11 patients). An additional 20% of patients achieved stable disease [139,140]. In the ECMM registry on mucormycosis patients the survival rate of patients receiving posaconazole was 72% [7]. A retrospective analysis of 96 published case reports of posaconazole treatment found a 73% complete response rate [141].

Other reports on salvage treatment cover series of smaller patient numbers (n = 2 to n = 323). Liposomal amphotericin B 5 mg/kg/day has been used in patients intolerant to previous amphotericin B deoxycholate treatment [105]. Amphotericin B lipid complex 5 mg/kg/day was given in some patients with refractory disease [130,142], in those intolerant to previous therapy or with pre-existing renal disease [130]. In the latter group, use of amphotericin B colloidal dispersion 5 mg/kg/day was also reported [143].

The combination of lipid-based amphotericin B plus caspofungin has been described in a few patients [135]. In models of neutropenic and ketoacidotic mice the combination of liposomal amphotericin B and posaconazole did not improve survival rates or reduce fungal tissue burden [144]. However, in a recent report on 32 patients with mainly haematological diseases, combinations of lipid-based, mostly liposomal, amphotericin B 3–5 mg/kg/day and posaconazole 800 mg/day were analysed [145]. Three months after

*Treatment duration is determined on a case-by-case basis and depends, for example, on extent of surgery and organs involved.

initiation of treatment 56% had responded to treatment [145].

Recommendations—For salvage treatment posaconazole 200 mg four times daily is strongly recommended, while lipid-based formulations of amphotericin B and combination of these two compounds are supported with moderate strength. For further recommendations refer to Table 9.

Specific patient settings

Children. Mucormycosis is a life-threatening disease in immunocompromised children and adolescents with haematological malignancies, transplantation, immunosuppressive therapy, diabetes, trauma or burns, and may also occur in premature neonates. Whereas gastrointestinal and cutaneous disease is the most common reported presentation in neonates, older children and adolescents typically present with pulmonary, rhino-orbito-cerebral, cutaneous, and disseminated disease. Overall mortality is 64% in neonates and 42–56% in children. Dissemination and age below one year are independent risk factors for death in children. Similar to adults, surgery combined with antifungal therapy is a factor associated with survival [121,146–149]. Of note, in a large epidemiological study from the USA, the incidence of mucormycosis was stable over time and no relationship to the increasing use of voriconazole among children was found [150].

Evidence—While the recommendations are similar to those for adults, there are, however, subtle but important differences for paediatric patients. These differences are consistent with paediatric development regulations and guidelines from the European Medicines Agency (EMA) whose concepts have been adopted by the 2012 ESCMID guideline for prevention and management of invasive Candida infections in neonates and children [151]. On the basis of this conceptual framework, the group considered four components for grading of therapeutic interventions: (i) evidence for efficacy from adult phase II trials and case series; (ii) existence and quality of paediatric pharmacokinetic data and dosing recommendations; (iii) specific paediatric safety data and supportive efficacy data; and (iv) regulatory approval for use in paediatric age group(s) [151].

Recommendations—Due to the absence of substantially different and/or separate paediatric data, recommendations for diagnosis (patient evaluation, diagnostic methods), principles of management (antifungal therapy, control of the predisposing condition, surgery), adjunctive treatments (granulocyte transfusions, cyto-
kines, hyperbaric oxygen, deferasirox), and timing/duration of antifungal treatment of paediatric mucormycosis are similar to those outlined for adults and are not recapitulated here.

Prompt initiation of treatment with amphotericin B and consideration of surgery are critical for successful management [121,146,148]. Based on observational data in adults [7,26,7,26,130,142,152], paediatric pharmacokinetics [153–155], safety data [148,154,156–159] and the existence of a paediatric label, the choices for first-line treatment in neonates, children and adolescents include amphotericin B lipid complex and liposomal amphotericin B. For pharmacokinetic and pharmacodynamic reasons liposomal amphotericin B is the preferred drug for infections involving the central nervous system [127]. While amphotericin B deoxycholate may have acceptable safety and tolerability profiles in neonates [160], its use is discouraged based on superior outcomes of lipid-amphotericin B in animal models and adults [124,136]. Predominantly due to the lack of clinical efficacy data in adults in this setting, posaconazole [7,26] and the combination of lipid-amphotericin B plus caspofungin [135] are only recommended with marginal strength for first-line therapy of paediatric patients.

Indications for salvage therapy include refractory disease and life-threatening toxicities of lipid amphotericin B; considering the high mortality of mucormycosis, pre-existing kidney dysfunction is not a priori a contraindication for treatment with lipid amphotericin B. Options for salvage therapy of mucormycosis in children ≥2 years and adolescents include posaconazole. This recommendation is based on adult efficacy data [122,139] and limited paediatric pharmacokinetic [161,162] and safety data [161–164]. Although no data for mucormycosis exist, demonstrating a trough serum concentration of 0.7–1.0 µg/mL is reasonable to assume exposure on the basis of treatment data obtained in patients with invasive aspergillosis [165]. Further options for salvage therapy include the combination of lipid amphotericin B plus caspofungin [121,135,166–170], both compounds are approved for all age groups, and the combination of lipid amphotericin B plus posaconazole for children ≥2 years of age [95,144]. Of note, posaconazole may also be used for consolidation treatment and as secondary prophylaxis, respectively. For further recommendations on first-line treatment refer to Table 10, and for salvage treatment refer to Table 11.

SoR, strength of recommendation; QoE, quality of evidence.

*aTreatment duration is determined on a case-by-case basis and depends, for example, on extent of surgery and organs involved.

*Thirty-three patients had both refractory disease and intolerance. 11 individuals are part of the Greenberg report, too.

*The reason for salvage treatment, i.e. refractoriness versus intolerance, was not reported in this study.

### Haematological malignancy

**Evidence**—With the intent to cure infection, granulocyte colony-stimulating factor has been applied to shorten neutropenia as the key predisposing factor for mucormycosis in this patient group. The results are difficult to interpret because of the small published patient numbers (n = 5 to n = 18) [3,105,171–175]. Granulocyte transfusion has been reported in an even more limited number of patients (n = 7 to n = 8) to cure mucormycosis [3,105,175]. Granulocyte transfusion has been combined with recombinant interferon-γ 1b (n = 4) [176].

**Recommendations**—In patients with neutropenia, granulocyte colony-stimulating factor is strongly recommended. The dose should be chosen as licensed. For further recommendations refer to Table 12.

### Solid organ transplant recipients

**Evidence**—In solid organ transplant recipients use of liposomal amphotericin B has been reported to be associated with increased response rates [25,177–179]. Specifically in pulmonary mucormycosis [177] and in sino-nasal-cerebral disease surgery was associated with...
increased survival rates [179].

**Recommendations**—In solid organ transplant recipients surgery and liposomal amphotericin B—usually in combination—are strongly recommended. For further recommendations refer to Table 13.

**HIV infection and AIDS. Evidence**—Mucormycosis may be found in human immunodeficiency virus (HIV)-infected patients; indeed, 2% of all mucormycosis patients in a large literature review were infected with HIV. However, HIV and AIDS are not considered risk factors specifically for mucormycosis [3].

**Recommendations**—Recommendations do not differ from other populations described above. In HIV patients drug–drug interactions of protease inhibitors and non-nucleoside reverse transcriptase inhibitors would need to be considered.

**Diabetes. Evidence**—Control of hyperglycaemia and ketoacidosis was suggested to be a beneficial reversal of a risk factor

</table>
for mucormycosis in a review of 145 patients (87 with diabetes) [180], and in two institutional cohorts of 35 and 33 diabetic patients [38,181].

Surgery was associated with improved cure and survival rates in a retrospective analysis of 101 patients with mucormycosis, 23 of these were diabetic patients with a 64% rate of rhinocerebral involvement [25]. Institutional cohorts of diabetic patients found surgery associated with increased survival rates [38,181]. Across these studies *Rhizopus oryzae* was the most frequently identified single pathogen [25,38,180,181].

**Recommendations**—In uncontrolled diabetes mellitus the control of hyperglycaemia and ketoacidosis is strongly supported. Surgery should be part of the therapeutic approach. For further recommendations refer to Table 14.

**Trauma patients. Evidence**—Trauma is the third major group of patients with mucormycosis [25]. Natural disaster and accidents are the usual settings [2,182]. In trauma patients mortality rates are lower than in patients with underlying haematological malignancy or diabetes [3,25]. In addition, trauma patients may be more likely to receive surgery and less likely to develop disseminated disease. Although a shorter duration of antifungal treatment may be feasible, a multimodal approach of surgical debridement (until clear margins) and antifungal treatment should improve response rates and has therefore been advocated [2,7,67,182].

**Recommendations**—Surgical debridement and antifungal treatment are strongly recommended in trauma patients with mucormycosis (Table 15).

**Adjunctive treatments and general management.** Iron overload may be a risk factor for mucormycosis [183,184], consequently iron depletion through chelators could be a useful adjunctive treatment.

**Evidence**—In murine models the iron chelator deferasirox protected from mucormycosis [183] and enhanced the efficacy of liposomal amphotericin B [185]. Furthermore, deferasirox was found to be safe in a phase II study in patients (n = 8) with proven mucormycosis [186]. However, when deferasirox was added to liposomal amphotericin B in a small (n = 20) prospective, double blind, placebo-controlled trial in haematological patients, the combination treatment group had a higher mortality rate (82% versus 22%) at 90 days [187]. These results are difficult to interpret and may have been caused by imbalanced baseline characteristics between the treatment groups. In any case, it is difficult to prescribe chelators in haematological patients with mucormycosis, although it is unclear whether other patient groups, e.g. diabetic patients

</table>
with rhinocerebral mucormycosis, are suitable for such treatment. This is one of the rare occasions when the group had to vote on a recommendation (Table 16).

Lovastatin inhibits the in vitro growth of *Rhizomucor pusillus* [188]. In a *Drosophila* model lovastatin had activity against *Mucor* sp. and *Rhizopus* sp., and exhibited a synergistic effect when combined with voriconazole, which species in the order *Mucorales* are intrinsically resistant [189]. It is unknown whether these observations are clinically meaningful.

Glucocorticosteroid treatment is a risk factor for fungal infection and in patients with mucormycosis it should be avoided. If this is not feasible then the dose should be reduced to the minimum required [190].

Hyperbaric oxygen has been reported in small numbers of patients in uncontrolled settings [3]. In a review of 28 published cases treated with adjunctive hyperbaric oxygen mortality was only 6%. Besides small patient numbers, bias in selecting patients suitable for the procedure, publication bias and generally lower survival rates in haematological patients limit the quality of evidence [107,191].

The optimal duration of treatment has not been studied prospectively and is generally unknown. Duration of any of the treatments above is based on individual decision.

**Recommendations**—In haematological patients with mucormycosis, adjunctive treatment with deferasirox is discouraged, whereas in other patient groups it is recommended with marginal strength. It is strongly recommended to stop glucocorticosteroid treatment in patients with mucormycosis. We strongly recommend continuing antifungal treatment until
